Резюме

Люцифераза светляков широко используется для анализа микробного загрязнения. Анализ основан на определении аденозин-5'-трифосфата (АТФ), концентрация которого прямо пропорциональна количеству живых клеток. В настоящей статье была исследована возможность применения биолюминесцентной системы светящихся бактерий NADH:FMN-оксидоредуктаза (Red) и люцифераза (BLuc) для количественного анализа бактериальных клеток путем определения никотинадениндинуклотида (NADH) и флавинмононуклотида (FMN). Предел чувствительности системы составил 1,2 нМ FMN и 0,1 пМ NADH. Экспериментальные данные показали, что с помощью системы Red и BLuc можно определить более 800 тысяч бактериальных клеток на миллилитр путем экстрагирования NADH из разрушенных клеток. Предложенный метод может применяться только для сильно загрязненных образцов.

Ключевые слова: NADH:FMN-оксидоредуктаза, бактериальная люцифераза, Бактериальное загрязнения, *Escherichia coli*

Bioluminescent System of Luminous Bacteria for Detection of Microbial Contamination

Abstract

Firefly luciferase is commonly used to detect bacterial contamination. The analysis is based on the detection of adenosine-5'-triphosphate (ATP) which is linearly correlated to the number of viable cells. In the present study a bioluminescent enzyme system of luminous bacteria NADH:FMN-oxidoreductase (Red) and luciferase (BLuc) was investigated to understand if it can be used for quantitative measurements of bacterial cells by nicotinamide adenine dinucleotide (NADH) and flavin mononucleotide (FMN) detection. The lowest limits of detection were 1.2 nM in case of FMN and 0.1 pM for NADH. The experimental results showed that Red and BLuc system could detect more than 800 thousand bacterial cells mL⁻¹ by determining concentration of NADH extracted from lysed cells. The method can be used only for highly contaminated samples.

Keywords: NADH:FMN-oxidoreductase, bacterial luciferase, bacterial contamination, *Escherichia coli*

Introduction

Detection of microbial contamination in food (Bottari et al., 2015) and beverages is one of the most important aspects (Frundzhyan et al., 2008) in food safety. Maintenance of proper hygienic environment in hospitals (Zambrano et al., 2014), kitchens and manufacturing units (e.g. food vessels, containers, food processing units) (Shama and Malik, 2013) is also the prerequisite to maintain a healthy atmosphere. In this regard, conventional methods that are commonly applied are plate count assay (PCA) (Lahtinen et al., 2006), polymerase chain reaction (PCR) (Turgay et al., 2016), broth dilution method (Wiegand et al., 2008), selective agar plating, etc.

A traditional PCA and related methods involve incubation of a sample in culture media for over two days to get meaningful results. Moreover, these routine microbiological methods require trained personnel and are laborious, expensive and less sensitive. Therefore, ATP bioluminescence method based on luciferin/luciferase reaction of fireflies has been widely used to monitor food hygiene and sanitary conditions. Indeed, adenosine triphosphate (ATP) is an excellent marker for cell viability and microbial contamination since it is universally present in all living organisms. Noda and co-authors reported a detection of a single bacterial cell using mutant firefly luciferase (Noda et al., 2008). Likewise, Mei et al. published a research paper which described how a bioluminescent enzyme system of luminous bacteria can be used for quantitative measurement of bacterial cells by means of nicotinamide adenine dinucleotide (NADH) detection (Mei et al., 2009). Similarly, flavin mononucleotide (FMN) can possibly emerge as a potential marker of microbial contamination since FMN and NADH are coenzymes which regulate a plenty of metabolic pathways in bacterial cells, and are also the substrates for a coupled enzyme system of luminous bacteria i.e. NADH:FMN-oxidoreductase (Red) and bacterial luciferase (BLuc). In current research, we studied the assay sensitivity of the coupled enzyme system of luminous bacteria (Red and BLuc) towards its substrates viz. FMN and NADH to implement it for the detection of microbial contamination using a standard bacterial strain.

Materials and Methods

Materials

Lyophilized bacterial luciferase (BLuc: EC 1.14.14.3) from *Photobacterium leiognathi* (recombinant strain of *Escherichia coli*) and NAD(P)H:FMN-oxidoreductase (Red: EC 1.6.99.3) from *Vibrio fischeri* were produced at the Institute of Biophysics (IBP), Siberian Branch of the Russian Academy of Sciences (SB RAS), Krasnoyarsk. NADH and FMN were the products of Serva, Germany while tetradecanal was procured from Merck, Germany. K_2HPO_4 and KH_2PO_4 were purchased from Medigen, Russia. *Escherichia coli* (*E. coli*) cells (BL21 codon Plus (DE3) RIPL) were used as a standard bacterial strain for real sample analysis. Bacterial cell lysis was carried out by an ultrasonicator (UZDN-2T, Russia). Luminescence measurements were performed using a luminometer (Lumat LB 9507, Berthold Technologies, Germany).

Methods

Biomass cultivation

A loopful of freshly cultured *E. coli* cells were taken from a slant and were transferred to 50 mL sterile Luria Bertini (LB) broth in an Erlenmeyer flask and cultivated at 30°C under shaking condition for 18 hours in an incubator shaker (New Brunswick Excella E25, Eppendorf, Germany). The approximate number of *E. coli* cells in the culture broth was measured using a UV-Vis spectrophotometer UVIKON 943 (Kontron Instruments, Italy) at 600 nm (1 O.D. = 5.0×10^8 cells mL^{-1}).

Preparation of standard reagents

A vial of lyophilized bacterial luciferase (BLuc) containing 0.5 mg of an active enzyme and a vial of lyophilized NADH:FMN oxidoreductase (0.15 U) were diluted in 50 mM phosphate buffer (pH 6.8) each to obtain concentration of 0.25 mg mL^{-1} and 0.15 U mL^{-1} , respectively. The diluted enzyme solutions were stored on ice throughout the experiment.

A stock solution of tetradecanal was prepared by taking a small amount of 50% tetradecanal in a glass vial followed by mild heating in a water bath till it melted completely.

Then, 25 μL of liquid tetradecanal was dissolved in absolute ethanol to obtain a concentration 0.25% and a final volume of 5 mL. The working solution was prepared by dissolving 50 μL of 0.25% tetradecanal solution in 5 mL of phosphate buffer (pH 6.8) to obtain the concentration of 0.0025%.

Stock solutions of 0.5 mM FMN and 0.5 mM NADH were prepared using distilled water and phosphate buffer (50 mM, pH 6.8) respectively. The working standards were prepared by further dilution of the stock solutions.

Luminescence measurements

Luminescence measurements were performed using the coupled enzyme system (Red and BLuc) in the presence of standard FMN (1 nM-10 μM) or NADH (0.1 pM -10 nM). The calibration curve for standard NADH was obtained by dispensing the reactants into a luminometric tube in the following sequence: 300 μL , phosphate buffer (50 mM, pH 6.8); 40 μL , BLuc; 10 μL , Red; 20 μL , 0.0025% tetradecanal and 10 μL , 0.1 mM FMN. The reaction mixture was evenly mixed in the tube and the luminescence baseline was recorded using a luminometer. Once the baseline was stabilized (approx. 6 minutes), 100 μL of standard NADH solutions were injected to plot a calibration curve. The maximum luminescence intensity (I_{max}) was noted in terms of relative luminescence units (RLU).

Similarly, a standard curve for FMN was plotted. The reaction mixture contained 300 μL , phosphate buffer (50 mM, pH 6.8); 5 μL , BLuc and Red; 50 μL , 0.0025% tetradecanal; 50 μL , 0.25 mM NADH. The reaction was initiated by injecting 10 μL FMN (1 nM-10 μM) in the tube, mixed evenly to measure the luminescence and plot the standard FMN curve.

Real sample analysis

Sample preparation for *E. coli* cells was carried out by using a) intact cells, b) sonicated cellular extract, and c) the clear supernatant of lysed *E. coli* cells. The samples were added to the reaction mixture instead of FMN or NADH. The baseline signal was measured every time before the sample was injected.

For the bacterial cell lysis, 1 mL of freshly cultivated *E. coli* cells (O.D.: 5.0×10^8 cells mL⁻¹) was suspended in a microfuge vial and sonicated at 44 kHz for 50 seconds with pauses for cooling after every 10 s. Further, 10 μ L of bacterial extract were added to the previously defined reaction mixture instead of FMN or NADH to determine their concentration by measuring luminescence intensity. The same assay procedure was applied to live intact *E. coli* cells and the clear supernatant which was obtained by centrifuging the sonicated vials at 5000 rpm, 25°C, for 10 min.

Results and discussion

Sensitivity of coupled enzyme system BLuc-Red to FMN and NADH

Detection of FMN and NADH at low concentrations requires optimization of reactants. Therefore, the optimized values of the reactants were obtained by varying their concentrations to detect ultrasensitive levels of NADH in the sample. The concentrations of the reactants in the tube were 10 μ g BLuc, 0.002 U Red, 1×10^{-4} % tetradecanal and 2 μ M FMN. Similarly, the optimal concentrations of the reactants in the assay mixture for FMN determination were 30 μ M NADH, 3×10^{-4} % tetradecanal, 0.63 μ g BLuc and 0.0002 U Red (data not shown). The limit of detection (LOD) for FMN and NADH was calculated using the BLuc-Red system and was found to be 1.2 nM FMN and 0.1 pM NADH.

During the assay, light emission was observed in the absence of NADH in the reaction mixture. That is the limiting factor of the detection system, and to minimize the signal, the reaction mixture was kept at room temperature for 6 minutes, after which NADH was added. The linear range for the NADH response curve was found to vary from 0.1 pM to 1 nM (Fig. 1a).

Previously, Jablonski and DeLuca had published the detection limit of 1 fM NADH (Jablonski and DeLuca, 1979) while Mei et al. detected only 0.1 nM NADH (Mei et al., 2009). The bioluminescent method of NADH detection is more sensitive than fluorescence spectrophotometry (Wang et al., 2009).

The standard curve for FMN is shown in Fig. 1b. Each point on the curve represents the mean value of four replicates for each measurement. The coupled enzyme system of luminous bacteria Red and BLuc was able to detect 1.2 nM FMN. The linear correlation between luminescence and FMN concentration was observed in the range from 1.2 nM to 10 μ M of FMN.

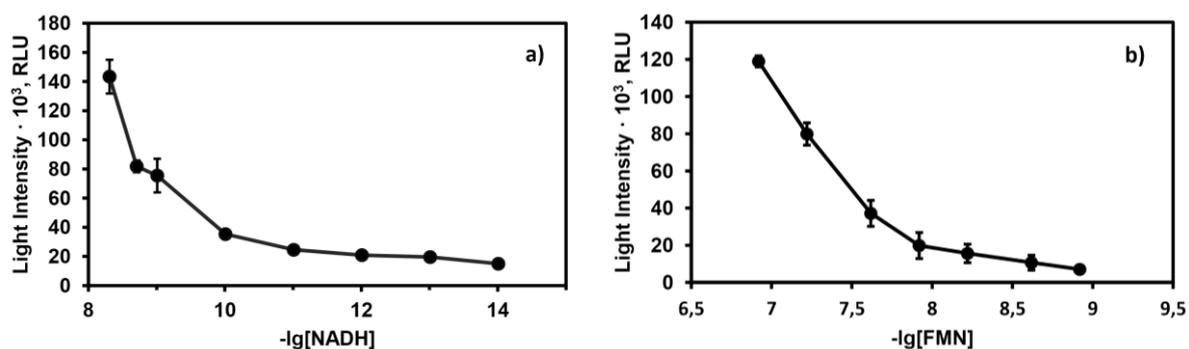

Figure 1. The calibration curve for a) NADH and b) FMN.

After the intact *E. Coli* cells were added to the assay mixture instead of FMN, the light intensity of the coupled enzyme system retained on the baseline level, which means the absence of FMN in the extracellular medium. Thus, it is impossible to use intact *E. Coli* cells for a quantitative analysis. However, a different scenario was observed when intact *E. Coli* cells were added to the reaction mixture instead of NADH. The increased luminescence output indicated the presence of NADH or other reductants in the medium.

The correlation between bioluminescence intensity and the number of cells was observed after a sonicated cell suspension was added to the assay mixture (Fig. 2). The limit of detection was determined as the number of cells when light intensity of coupled enzyme system Red and BLuc was found to be three times higher than the baseline luminescence.

The sensitivity of the bioluminescent system was found to be 3.9 million cells mL⁻¹ and 800 thousand cells mL⁻¹ obtained through the detection of FMN and NADH, respectively. Centrifugation as an additional step of sample preparation did not improve the sensitivity of the method. The lowest limit of detection after centrifuged supernatant addition was about 5 million

cells mL⁻¹. The obtained results correlate with data published by Liu et al. who had achieved the level of 1.05×10^5 cells mL⁻¹ by converting NAD⁺ to NADH (Liu et al., 2014).

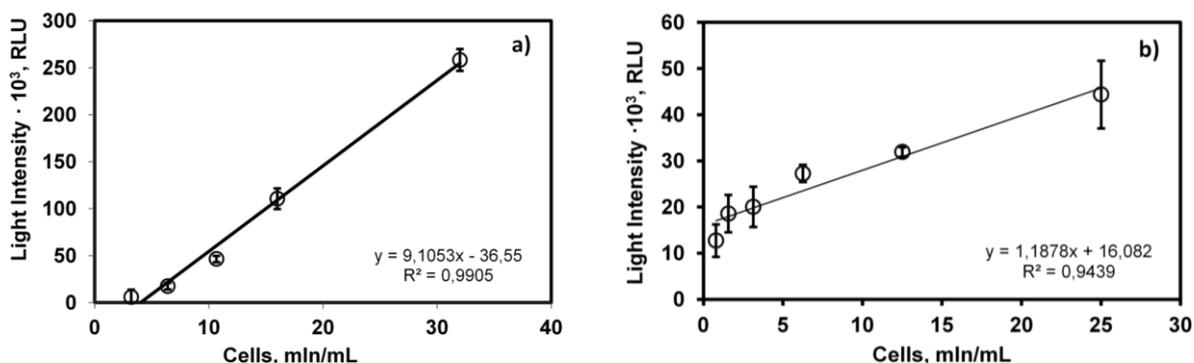

Figure 2. Correlation between bioluminescence intensity and lysed cells number in the reaction mixture a) FMN determination; b) NADH determination.

4. Conclusions

There is a wide range of CFUs detection methods, from microbiological (PCA) to genomic (quantitative PCR, etc.). PCA is thought to be the most popular among them although the conventional plate methods have a number of drawbacks. Thus, bioluminescent methods are gaining popularity as they prove to be rather convenient in analysing bacterial contamination. In this regard, firefly luciferase is widely used to control a food safety or sterility.

In this research we proved the possibility of coupled enzyme system of luminous bacteria (Red and BLuc) to be used for the detection of microbial contamination. We showed that the system Red and BLuc is able to detect at least 800 thousand bacterial cells mL⁻¹. The analysis was based on determining NADH concentrations. The sample processing that was used in the study includes sonication and does not require centrifugation. So the Red and BLuc system can be used for detection of microbial cells in highly contaminated samples.
